Abstract

Three different ordered mesoporous silica materials, such as MCM-41, Al containing MCM-41 (mass ratio Si/Al = 10) and SBA-15, were prepared. In a next step, cobalt (5-8 wt%) as an active metal for redox reactions, was introduced by the impregnation. The prepared catalysts were characterized by AAS, EDX, N₂ physisorption, XRD, DR UV-Vis spectroscopy, Raman spectroscopy, TPR-H₂ and their catalytic properties were evaluated for N₂O decomposition and reduction. The catalysts showed poor activity in N₂O decomposition while the use of reducing agent (carbon monoxide) was beneficial for their catalytic activities. The lowest catalytic activity showed Co/Al-MCM indicating that the aggregated CoₓOᵧ species present in this catalyst were inactive and not beneficial for the catalytic activity.

Keywords

Mesoporous ordered silica; Aluminum; Cobalt; Impregnation; N₂O decomposition

1 INTRODUCTION

The exceptional activity of noble metals (such as Au, Rh or Ru) for the catalytic reactions such as N₂O decomposition [1, 2, 3] has been studied. However, due to the excessive cost of noble metals, the interest is paid to the use of transition metal oxide catalysts [4]. The range of papers dealing with the catalytic performance of mesoporous silica materials modified with cobalt has been published [5, 6, 7, 8, 9, 10].

The metal site isolation can be achieved by simple deposition of the metal precursor using wet impregnation. However, the impregnation method often results in catalysts with broader distribution of metal species and lower degree of dispersion or bulk oxide. Metal acetylacetonate (acac) complex such as VO(acac)₂ was used for the wet impregnation of vanadium on hexagonal mesoporous silica (HMS) as reported by Bulanek and co-authors [11]. The similar approach was applied in our study. As reported in the papers [12, 13], the adsorption of Co(acac)₂ complexes led to the precipitation of cobalt oxides on alumina surface. On the other hand, the stability of Co(acac)₂ was beneficial to form a high loading of cobalt on silica surface.

Aluminum is known as an element generating acid sites by substitution of Si by Al in the silica structure. Aluminum can enhance the dispersion, localization and stability of metal nanoparticles (such as Fe, Ru, Rh or Au) on silica surface such as SBA-15 or SiO₂ extracted from the natural clay [3, 14].

To our knowledge, the catalysts prepared by impregnation of Co(acac)₂ on ordered mesoporous silica materials (MCM-41, MCM-41 with incorporated aluminum and SBA-15) and tested in N₂O catalytic decomposition and reduction by using CO as the reducing agent have not been reported yet. The aim of the paper is to find the relation among physicochemical properties of cobalt deposited on different supports and the performance of these materials in the above mentioned catalytic reactions. The main interest is focused on the differences in (i)
textural and structural properties of catalysts supports, (ii) crystalline phase, (iii) coordination and oxidation state of cobalt cations and (iv) reducibility of catalysts.

2.1 Synthesis of mesoporous silica supports

MCM-41 material was prepared by a direct interaction between an ionic, positively charged surfactant and a negatively charged silica source in a basic environment. The synthesis of MCM-41 was performed according to [15] by using cetyltrimethylammonium bromide (C_{16}TMABr), ammonia (30 wt% solution of NH_{3} in H_{2}O), tetraethyl orthosilicate (98 % TEOS) and water.

Synthesis of Al-MCM-41 was done according to [16]. Sodium hydroxide (NaOH), cetyltrimethylammonium bromide (CTABr, C_{16}H_{33}(CH_{3})_{3}Br), tetraethylorthosilicate (TEOS), aluminum sulphate (Al_{2}(SO)_{4}18H_{2}O), and deionized water were used.

SBA-15 material was prepared by use of block copolymeric surfactant that interacts with the positively charged silica source in acid medium. SBA-15 was synthesized as described in [17] in acidic conditions using polyethyleneoxide-polypropyleneoxide-polyethyleneoxide copolymer (EO_{20}PO_{70}EO_{20}), hydrochloric acid (37 % HCl), tetraethyl orthosilicate (98 % TEOS) and water.

2.2 Preparation of catalysts

The calcined silica support was dried in an oven at 200 °C in the air atmosphere. The appropriate amount of Co(acac)_{2} was dissolved in ethanol. Afterwards, the calculated amount of support was added to the solution which was stirred at 80 °C till ethanol slowly evaporated. Finally, the formed suspension was dried in the oven at 120 °C and calcined at 550 °C with a heating rate of 1 °C.min^{-1} in the period of 12 h.

The prepared catalysts are designed as: (i) Co/MCM, (ii) Co/Al-MCM, and (iii) Co/SBA.

2.3 Characterization techniques

The metal loadings were determined by an electron dispersive X-ray (EDX) analyzer XL30 Phillips and by an atomic absorption spectrometer (AAS) Spectr AA880 (Varian). For AAS analysis, the catalysts were dried, dissolved in 3 ml HCl and heated up.

Textural properties of the samples were determined by nitrogen sorption measurements at -196 °C using a QuadraSorb SI MP Station. Prior to the measurements, the samples were degassed under vacuum at 200 °C for 16 h. The mesopore diameter was determined from the maximum of pore size distribution curve of BJH method. The microporosity was evaluated by t-plot method using de Boer for oxidic silicas.

The XRD patterns in 2θ range from 10 to 80° were recorded under CoKα irradiation (λ = 1.789 Å) using the Bruker D8 Advance diffractometer (Bruker AXS) equipped with a fast position sensitive detector VANTEC 1. Measurements were carried out in the reflection mode, powder samples were pressed in a rotational holder, goniometer with the Bragg-Brentano geometry in 2θ range from 5 to 60°. Phase composition was evaluated using database PDF-2 Release 2011 (International Centre for Diffraction Data).

Diffuse reflectance UV–Vis spectra of the powder samples were recorded in the range 190 – 900 nm (11111 - 50000 cm^{-1}) at room temperature on the Cintra 303 equipped with a diffuse reflectance attachment.

Raman spectra were measured by Smart Raman Microscopy System XploRA™ (HORIBA Jobin Yvon, France). Raman spectra were acquired with 532 nm excitation laser source, and 2400 groove/mm grating in the range 150 – 1100 cm^{-1}. Raman spectra were acquired at each of at least 5 points.

Temperature programmed reduction by hydrogen (TPR-H_{2}) was carried out on AutoChem II 2920 on the powder samples of the grain 0.160-0.315 mm. The TPR runs were performed in the flow of 10 vol% H_{2}/Ar (50 ml.min^{-1}) with the heating rate 20 °C.min^{-1} in the temperature range 25-1000 °C. The hydrogen consumption was monitored by thermal conductivity detector (TCD).

The cobalt standards CoO (Alfa Aesar, CAS: 1307-96-6, purity 95 %), Co_{3}O_{4} (Alfa Aesar, CAS: 1308-06-1, purity 99.7 %) and CoAl_{2}O_{4} (Alfa Aesar, CAS: 12672-27-4, Co 39-41 %) were applied.
2.4 Catalytic tests

The catalytic tests were performed in an integral fixed bed stainless steel reactor of 5 mm internal diameter in the temperature range from 390–450 °C under atmospheric pressure. The catalyst bed contained 0.1 g of catalyst with a particle size of 0.160–0.315 mm. The weight hourly space velocity (WHSV) of 60 000 l h⁻¹ kg⁻¹ (GHSV = 15648 h⁻¹) was applied. The feed introduced to the reactor contained (i) 0.1 mol% N₂O in nitrogen and (ii) 0.1 mol% N₂O and 0.1 mol% CO in nitrogen. A gas chromatograph equipped with a thermal conductivity detector (TCD) (Agilent Technologies 7890A) and the chromatographic column ShinCarbon Micropacked (dimension: 2 m x 0.53 mm, oven program: 100 °C for 2 min then 40 °C/min to 250 °C for 1 min) was used for N₂O analysis.

3 RESULTS AND DISCUSSION Characterization of catalysts

Theoretical and experimental Si/Al ratio, initial loadings of Co(acac)₂, theoretical concentration of Co and final concentrations of Co and Al determined by EDX and AAS analyses are displayed in Table 1. AAS measured the bulk concentration of cobalt and is more precise than EPMA measuring only surface concentration of cobalt. The concentration of cobalt determined by AAS is considered for further comparison of catalysts.

The Co spinel phase was surely detected in Co/Al-MCM catalyst. XRD patterns of other catalysts are noisy for the determination of Co spinel phase. Due to the similar reflection angles and intensities in XRD, it is not possible to distinguish between Co₃O₄ (PDF number 65-3103), CoAl₂O₄ (PDF number 03-0896) and Co₂AlO₄ (PDF number 02-1410). As depicted in Fig. 1, the peak of amorphous SiO₂ at the maximum 2θ = 27 ° is the most apparent in Co/SBA catalyst.

The DR UV-Vis spectra are used for the characterization of the nature and the coordination of cobalt oxide species. Triplet absorption bands at around 15550, 17094, 19120 cm⁻¹ are assigned to 4A₂(F) → 4T₁(P) transition of Co(II) species in tetrahedral coordination geometry, see Fig. 2 [18, 19, 20].

The absorption band at 13642 and 23310 cm⁻¹ are attributed to non-specified oxide Co₂O₇, as it is obvious in Fig. 2 [20, 21]. These bands are evident in Co/Al-MCM.

Raman spectroscopy is much more sensitive for the detection of small crystalline clusters than XRD analysis [22]. Fig. 3 shows Raman spectra of Co-impregnated catalysts where five bands at 194, 479, 520, 612, and 682
cm⁻¹ are clearly visible. According to the literature [23], these bands correspond to symmetric vibrational modes \( F_{2g}, E_g, F_{2g}, \) and \( A_{1g} \) and predict the formation of microcrystallites of \( \text{Co}_3\text{O}_4 \). The measured Raman spectra of cobalt standards \( \text{Co}_3\text{O}_4, \text{CoO} \) and \( \text{CoAl}_2\text{O}_4 \) are shown in Fig. 4. By comparison of the spectra, the determination of \( \text{Co}_3\text{O}_4 \) and/or \( \text{CoO} \) is difficult due to their similar spectra as well as the position of the bands in Co-impregnated catalysts could be affected by the presence of supports. The phase \( \text{CoAl}_2\text{O}_4 \) is not present in the catalysts by comparison of Figs. 3, 4 as well as \( \text{Co}_2\text{AlO}_4 \) and \( \text{NaCo}_2\text{O}_4 \) are not present, according to the literature [24].

The results from TPR-\( \text{H}_2 \) of Co-impregnated catalysts and cobalt standards are summarized in Table 3. The TPR profiles are depicted in Fig. 5. The low-temperature reduction peaks (25–500 °C) correspond to the reduction of \( \text{Co}^{\text{III}} \rightarrow \text{Co}^{\text{II}} \) and/or \( \text{Co}^{\text{II}} \rightarrow \text{Co}^{0} \) in cobalt oxides [25]. The highest amount of easily reducible cobalt species was present in Co/Al-MCM indicating that the sintering of Co particles into aggregates was favored in this catalyst. The high-temperature reduction peaks (530–1000 °C) are assigned to \( \text{Co}^{2+} \) ions interacting strongly with the support and to the reduction of surface Co silicate [10, 26]. The broad second reduction peak with \( T_{\text{max}} \) 709 °C in the catalyst Co/Al-MCM indicates less uniform cobalt ion distribution in the silica framework [9]. Compared to that, Co/MCM and Co/SBA catalysts showed significant shift of \( T_{\text{max}} \) to higher temperature indicating higher reduction stability of these catalysts.

3.2 Catalytic activity in N₂O decomposition and reduction

The Co-impregnated catalysts were tested in N₂O decomposition. The N₂O conversion (X<sub>N₂O</sub>) at 450 °C was in the order: Co/SBA > Co/Al-MCM > Co/MCM which indicates no catalytic activity in N₂O decomposition for all catalysts.

The rate determining step of catalytic decomposition of N₂O (Eq. 1) is supposed to be the reduction of active sites to remove adsorbed oxygen species which remain on the surface after dissociation of N₂O molecule.

\[ \text{N}_2\text{O} \rightarrow \text{N}_2 + \frac{1}{2} \text{O}_2 \] (1)

Therefore, reducing agent (such as carbon monoxide) could facilitate desorption of oxygen species and hence the rate of N₂O decomposition (Eq. 2).

\[ \text{N}_2\text{O} + \text{CO} \rightarrow \text{N}_2 + \text{CO}_2 \] (2)

The reducing agent increased the activity (X<sub>N₂O</sub> at 450 °C) which was in the order: Co/SBA > Co/MCM > Co/Al-MCM. The catalytic activity expressed by TOF (turnover frequency) as the number of N₂O molecules reacting in unit time per active cobalt site defined by AAS [27] was at 450 °C in the order: Co/SBA > Co/MCM > Co/Al-MCM reflecting the highest activity of Co/SBA catalyst. The Co/SBA catalyst does not differ from Co/MCM from the point of view of the coordination and oxidation state of cobalt assigned to surface Co(II) species in tetrahedral coordination geometry. Therefore, the reason for higher activity can be due to different particle size of cobalt and its dispersion on silica supports. The Co/Al-MCM differs from the others indicating the presence of aggregated Co₃O₄ species which showed up to be inactive and not beneficial for the catalytic N₂O decomposition and reduction even though the reducibility below 500 °C was the highest for Co/Al-MCM.

4 CONCLUSIONS

The impregnation method was applied for the deposition of cobalt on three different mesoporous silica supports: MCM-41, MCM-41 with aluminum incorporated into the silica framework (Al-MCM-41) and SBA-15.

The presence of tetrahedral Co(II) was detected for all prepared catalysts, however, the presence of aggregated crystalline Co₃O₄ species was analyzed by XRD, DR UV-Vis and TPR-H₂ in Co/Al-MCM. There is no clear determination by Raman spectroscopy of CoO or Co₃O₄ crystalline phase.

The catalysts showed no activity in the reaction of N₂O decomposition whereas the use of reducing agent (carbon monoxide) increased their catalytic activities. However, N₂O conversion did not exceed 37 % at 450°C in the case of Co/SBA. The lowest catalytic activity showed Co/Al-MCM indicating that aggregated Co₃O₄ species on the surface of Co/Al-MCM were inactive and not beneficial for the catalytic activity.
